Received: April 14, 2000; In Final Form: August 14, 2000

The low-lying electronic states of  $\text{NbC}_n$  with five different geometries, namely, ring (R), linear (L), kite (K), Nb-terminally bound to a  $C_n$  ring (T), and a structure with C–Nb–C bridge fused with a  $C_n$  ring (A) ( $n > 3$ ) are considered for  $n = 3-8$ . Three different levels of theoretical techniques, viz., complete active space multiconfiguration self-consistent field, multireference singles + doubles configuration interaction, and density functional theory were considered. We compute the equilibrium geometries, energy separations of the low-lying electronic states, Gibbs free energies, and heat capacity functions as a function of temperatures. For smaller clusters such as  $\text{NbC}_3$ ,  $\text{NbC}_4$ , and  $\text{NbC}_5$ , we find the ring structure to be lower with the linear structure as the first excited structure. Larger clusters exhibit odd–even alternation in that for even  $n$  the linear and ring structures are very close, whereas the clusters with odd  $n$  exhibit lower ring structures analogous to the smaller clusters.  $\text{NbC}_6$  was found to be unusual in having a linear ground state.

## I. Introduction

Transition metal carbides have a long and rich history of experimental and theoretical studies.<sup>1–46</sup> A possible motivation for these studies is that the transition metal catalysts find extensive use in reforming petroleum-based products. Thus, there is a compelling need to comprehend the nature of metal–carbon bonds, as this could aid in the understanding of catalytic selectivity and mechanisms. Although earlier experimental studies were carried out using the Knudsen effusion technique combined with mass spectrometry,<sup>4–7</sup> more recent studies have included the ion drift tube technique,<sup>2,9–11</sup> electron spin resonance spectroscopy<sup>14–17</sup> of rare-gas matrix isolated carbides, and high-resolution optical spectroscopy.<sup>12,13,18–22</sup> Larger transition metal carbide clusters such as  $\text{LaC}_n^{+2}$  and  $\text{TaC}_n^{+3,40}$  have also been studied for many values of  $n$ . High-resolution optical spectroscopic techniques have been employed on diatomic carbides containing second row transition metal atoms such as  $\text{YC}$ ,<sup>13</sup>  $\text{NbC}$ ,<sup>12</sup> and  $\text{PdC}$ .<sup>19</sup> Photoelectron spectroscopy of the anion has also yielded information on the neutral  $\text{WC}$ .<sup>18</sup> The matrix-isolated ESR spectroscopy has been utilized on second-row transition metal carbides.<sup>14–17</sup>

There is also significant interest on larger transition metal carbon clusters such as metallofullerenes,<sup>1</sup> metallocarbohedranes, and unusually stable “metcars”,<sup>39</sup> as these species exhibit unusual stability and bonding characteristics with potential industrial applications. A recent review article of Rohmer et al.<sup>5</sup> summarizes advances pertinent to not only larger transition metal carbides such as metcars but also smaller transition metal carbides.

There have been several experimental studies on niobium carbides and their ions. The mass spectroscopic studies made by Duncan and co-workers<sup>42</sup> as well as Castleman and co-workers<sup>41</sup> have revealed that among the smaller  $\text{Nb}_n\text{C}_n^+$  clusters,

especially for  $n = 2-4$ , are particularly stable. The binding energies with  $-\text{OH}$  and  $-\text{OCH}_3$  groups have been estimated for the niobium carbide clusters with abstraction reactions between  $\text{H}_2\text{O}$  and  $\text{Nb}_4\text{C}_4^+$ . Larger Niobium carbide clusters with two types of compositions have been found to be especially very abundant, and they correspond to metcars and fcc crystallites.

Spectroscopic studies on smaller niobium carbides include the matrix-isolated ESR spectroscopy of  $\text{NbC}$  by Hamrick and Weltner,<sup>14</sup> which have yielded the spin multiplicity of the ground state of the diatomic  $\text{NbC}$ . Simard and co-workers<sup>12</sup> have obtained the spectroscopic constants of several low-lying electronic states of the diatomic  $\text{NbC}$  through optical spectroscopy.

Theoretical studies have been focused primarily on the second-row transition metal carbides such as  $\text{YC}$ ,<sup>8</sup>  $\text{MoC}$ ,<sup>35</sup>  $\text{RuC}$ ,<sup>34</sup>  $\text{RhC}$ ,<sup>29</sup> and  $\text{PdC}$ .<sup>32,33,36–38</sup> The earlier studies have been typically made using the Hartree–Fock/Configuration interaction (HF/CI) techniques.<sup>8,32–35</sup> The  $\text{RhC}$ <sup>29</sup> and  $\text{PdC}$ <sup>38</sup> diatomics have been studied using complete active space multiconfiguration self-consistent field (CAS-MCSCF) followed by multireference singles + doubles configuration interaction (MRSDCI) techniques. There have been a few studies from our laboratory<sup>23–26</sup> on transition metal carbides containing multiple number of carbon atoms such as  $\text{YC}_n$ ,  $\text{TaC}_n$ ,  $\text{LaC}_n$ , etc. There have also been RHF and MP2 studies on  $\text{Nb}_4\text{C}_4$  cluster and its cation.<sup>43</sup> Among other transition metal carbides, there have extensive number of studies on iron carbides.<sup>44–46</sup>

The relative energy ordering of the electronic states is often uncertain, as different levels of theory do not always yield the same information. This is a consequence of a large number of low-lying electronic states of different spin multiplicities and spatial symmetries for transition metal carbides. There is a competition between spin exchange stabilization and electron correlation. The spin exchange stabilization favors the high spin electronic states, whereas electron correlation effects stabilize the low-spin electronic states, and thus, the competition between

<sup>†</sup> Department of Chemistry and Biochemistry, Arizona State University.

<sup>‡</sup> Institute of Physical and Theoretical Chemistry, Wrocław University of Technology.

the two stabilization features places the electronic states at different relative energies at different levels of theory. In addition, relativistic effects<sup>47</sup> make significant contributions to the second and third row transition metal carbides.

Although the diatomic NbC has been studied experimentally before, this is not the case with larger NbC<sub>n</sub> clusters. At present, very little information is available on larger clusters. The above survey reveals significant current interest in transition metal carbides. These species exhibit a large number of low-lying quartet and doublet electronic states and the nature of bonding in these states seem to differ due to differences in the participation of Nb(4d), Nb(5s), and Nb(5p) orbitals. We also calibrate the utility of the density functional theory (DFT) and the CASMCSCF/MRSDCI techniques for these carbides. The objectives of the current study are computations of the equilibrium geometries and energy separations of the NbC<sub>n</sub> clusters. We have also computed the thermodynamic properties (enthalpies and Gibbs free energies) of these species. We have investigated several low-lying high spin and low spin electronic states at the CASMCSCF and MRSDCI levels that included multi-million configurations. We have also carried out computations at the DFT level for the low-lying electronic states to facilitate comparison of the DFT and CASMCSCF/MRSDCI techniques.

## II. Method of Calculation

The niobium carbide clusters have been studied at different levels of theory here. Although for all clusters, a variety of structures were considered at the density functional level of theory (DFT), for the NbC<sub>n</sub> ( $n = 3-6$ ) clusters, the CASMCSCF technique was followed by the MRSDCI scheme was utilized. The CASMCSCF/MRSDCI techniques were used to gauge the accuracy of the DFT technique. The DFT technique was employed in conjunction with Becke's<sup>55</sup> three-parameter hybrid method using the LYP correlation functional (B3LYP). Geometries of different low-lying electronic states often with different spin multiplicities were optimized at the B3LYP, CASMCSCF, and MRSDCI levels, whereas the vibrational frequencies were calculated at the B3LYP level.

All of the computations were carried out using relativistic effective core potentials (RECPs) for the Nb atom taken from La John et al.,<sup>48</sup> which retained the outer 4s<sup>2</sup>4p<sup>6</sup>4d<sup>4</sup>5s<sup>1</sup> shells of the niobium atom in the valence space, replacing the remaining core electrons by RECPs. The RECPs for the carbon atom retained the outer 2s<sup>2</sup>2p<sup>2</sup> shells in the valence space. The optimized valence (5s5p4d) Gaussian basis sets for the Nb atom were taken from ref 48. The (4s4p) optimized Gaussian basis sets for the carbon atoms were contracted to (3s3p). The carbon basis set was supplemented with a set of six-component 3d functions with  $\alpha_d = 0.75$ . Our final basis sets are (5s5p4d) for the Nb atom and (3s3p1d) for the carbon atoms. The effect of 4f functions was studied,<sup>31</sup> and it was found that the inclusion of 4f functions change the M-C bond lengths by 0.01 Å and relative energy separations by 0.01–0.1 eV. Consequently, we do not anticipate the 4f type of functions to make significant contributions.

Different types of structures, such as the ring, kite, linear, ring with tail, and fused bicyclic structures, were considered. Full geometry optimization was considered for each of these structures for different electronic states. Using these data, the thermodynamic properties such as the Gibbs free energies and heat content functions were computed. The vibrational frequencies and IR intensities were also computed for the minimal

energy structures, and the existence of all real frequencies confirm that the minimal geometries report here were true minima.

The CASMCSCF computations of the clusters followed by MRSDCI computations were carried out for the smaller NbC<sub>n</sub> clusters with  $n = 3-6$  in order to gauge the accuracy of the DFT computations. On the basis of the accuracy, the DFT technique was employed for all of the clusters considered here. Separate CASMCSCF calculations for the electronic states of different spatial symmetries and spin multiplicities were carried out. These computations were carried out in the  $C_{2v}$  group as all of the structures considered here have at least  $C_{2v}$  symmetry. The 4s and 4p orbitals of the Nb atom that correlate into two a<sub>1</sub>, one b<sub>2</sub>, one b<sub>1</sub> orbitals were kept inactive in that no excitations from these shells were allowed but they were allowed to relax. Among the remaining orbitals, up to 9 orbitals were included in the active space (8–10 inactive orbitals) so as to represent all of the electronic states of NbC<sub>n</sub> adequately. Up to 11 active electrons were distributed in all possible ways among the active orbitals in CASMCSCF. The remaining electrons were kept inactive. Let a quadruple of numbers represent the number of orbitals in a<sub>1</sub>, b<sub>2</sub>, b<sub>1</sub>, and a<sub>2</sub> irreducible representations of the  $C_{2v}$  group. For NbC<sub>3</sub>, the of inactive orbitals are given by  $N_i = 3\ 2\ 2\ 0$  and the number of active orbitals are given by  $N_a = 4\ 2\ 2\ 1$ . The corresponding quadruples for NbC<sub>4</sub> are  $N_i = 5\ 2\ 2\ 0$  and  $N_a = 4\ 2\ 2\ 1$ . For NbC<sub>5</sub> these numbers are given by  $N_i = 5\ 3\ 2\ 1$  and  $N_a = 4\ 2\ 2\ 1$ . In summary, the CASMCSCF computations were carried out with sufficient flexibility yet keeping the orbital space manageable so that the number of configuration spin functions (CSFs) is not too big.

Following CASMCSCF, MRSDCI calculations were carried out for all of the low-lying quartet, doublet and sextet electronic states of NbC<sub>n</sub> to include the effects of higher-order electron correlation effects. The reference configurations for the MRSDCI computations were chosen from the CASMCSCF calculations with absolute coefficients  $\geq 0.07$ . All possible single and double excitations were allowed at the MRSDCI. The MRSDCI computations included a multi-million-configuration space. The DFT/B3LYP<sup>55</sup> computations were made with the Gaussian 98 codes.<sup>56</sup>

The spin-orbit effects were estimated for NbC<sub>2</sub> on the basis of the Nb atomic spin-orbit splittings<sup>57</sup> and the contribution of the Nb orbitals to the open-shell orbitals of NbC<sub>2</sub>. The spin-orbit effects were found to be rather small if the carbon orbitals make substantial contribution to the open-shell orbitals since the spin-orbit effects on the carbons<sup>57</sup> are less than 100 cm<sup>-1</sup>.

All CASMCSCF/MRSDCI calculations were made using a modified version<sup>52</sup> of ALCHEMY II codes<sup>51</sup> to include the RECPs.

## III. Results and Discussion

The electronic states of niobium carbides could arise from the Nb(4F) ground state or the low-lying Nb doublet electronic state<sup>57</sup> and one of the low-lying singlet or triplet states of the naked C<sub>n</sub> cluster. This would result in quartet, doublet and sextet electronic states for NbC<sub>n</sub>. We expect the sextet states to be higher in energy on the basis of our previous electronic structure studies on NbC<sub>2</sub>.<sup>31</sup> We have thus considered exhaustive study of the doublet, quartet, and sextet electronic states for these species. We have considered four kinds of structures for all of the electronic states. These structures are (1) a ring structure (R) in which the Nb atom is inserted in to the C<sub>n</sub> ring and it is part of the ring as in Figure 1, (2) the Nb atom is at the terminal of a linear structure (L) (3) a tail of carbon atoms attached to a

<sup>a</sup> For the R structure, a<sub>1</sub> represents the bond angle of C<sub>1</sub>–Nb–C<sub>2</sub>, a<sub>2</sub> represents the bond angle of C<sub>1</sub>–C<sub>3</sub>–C<sub>2</sub>. For the K structure, a<sub>1</sub> represents the bond angle of C<sub>1</sub>–Nb–C<sub>2</sub>, a<sub>2</sub> represents the bond angle of C<sub>1</sub>–C<sub>3</sub>–C<sub>2</sub>. For the T structure, a<sub>1</sub> represents the bond angle of Nb–C<sub>1</sub>–C<sub>2</sub> and Nb–C<sub>1</sub>–C<sub>3</sub>, a<sub>2</sub> represents the bond angle of C<sub>2</sub>–C<sub>1</sub>–C<sub>3</sub>.

**Figure 1.** Geometries of NbC<sub>n</sub> considered here.

four-member ring containing the Nb atom which we call the kite structure (K) as in Figure 1, (3) Nb bound terminally as a pending bond to a cyclic C<sub>n</sub> structure (T; Figure 1), and (4) a bicyclic fused system containing a C–Nb–C triangular ring. As we shall see from our results, some of these structures are viable candidates for the low-lying electronic structures of these clusters.

Although there appears to be no experimental studies on larger NbC<sub>n</sub> clusters, there have been a few experimental studies on LaC<sub>n</sub> and YC<sub>n</sub> clusters.<sup>2,5,10,11</sup> The experimental studies of Jarrold and co-workers<sup>2</sup> particularly on the LaC<sub>n</sub><sup>+</sup> clusters have suggested the possibility of competing linear and ring-like structures for LaC<sub>n</sub>. Analogous to this, there is also competition between structures in which the Nb atom is inside the ring versus structures in which Nb is exteriorly attached to the carbon ring. Because the species that we consider here have relatively small number of carbon atoms, stable rings could be formed with Nb

<sup>a</sup> Vertical(a) at the equilibrium geometry of the <sup>2</sup>A<sub>1</sub> state of the ring structure from B3LYP. <sup>b</sup> Vertical(b) at the equilibrium geometry of the <sup>4</sup>B<sub>2</sub> state of the ring structure from B3LYP.

included inside the ring, rather than pure carbon rings with metal atoms attached to it. More complex structures, such as the kite structure (K in Figure 1) for medium-sized clusters are also feasible. The geometries of all of these structures were optimized at the DFT/B3LYP level of theory. Note that although we allowed for full geometry optimizations, the minimal energy structures were found to be planar for all of the smaller clusters considered here. This is not surprising in that all smaller C<sub>n</sub> clusters are indeed planar as the planar structures support multiple bonding for smaller carbon clusters. Of course for larger carbon clusters fullerene cages are feasible, but such closed structures are not attainable for fewer than 20 carbon atoms.

**NbC<sub>3</sub>.** The optimized structures for the three spin states are presented in Table 1 for NbC<sub>3</sub> for all four geometries that we have considered. As seen from Table 1, the <sup>2</sup>A<sub>1</sub> state with a ring structure (Figure 1) of C<sub>2v</sub> symmetry is the lowest in energy. The <sup>4</sup>B<sub>2</sub> state with the same structure is 0.98 eV higher in energy, indicating a preference for a low spin ground state, even though the ground state of Nb is a <sup>4</sup>F state. The sextet state with a ring structure is not a viable candidate, although the linear structure exhibits a lower <sup>6</sup>Σ state. It is also interesting that only the ring structure exhibits doublet state as the lowest, whereas other structures exhibit quartet or sextet electronic states as the lowest states for those structures.

Table 2 shows the results of the CASMCSF/MRSDCI computations for several electronic states of NbC<sub>3</sub> with a ring structure. As seen from Table 2, the adiabatic CASMCSF energy separation of 0.94 eV for the <sup>4</sup>B<sub>2</sub> state is very close to the DFT/B3LYP result of 0.98 eV for the same state relative to the ground state. Table 2 also reports vertical energy separations of many electronic states. Evidently, there are other very low-lying states such as <sup>4</sup>A<sub>2</sub> close to the <sup>4</sup>B<sub>2</sub> state.

<sup>a</sup> Vertical(a) at the equilibrium geometry of the <sup>4</sup>B<sub>1</sub> state of the ring structure from B3LYP. <sup>b</sup> Vertical(b) at the equilibrium geometry of the <sup>2</sup>A<sub>1</sub> state of the ring structure from B3LYP.

In previous studies on LaC<sub>n</sub><sup>23,25</sup> we have compared the results of the DFT calculations with those of MP2 and found that the DFT results are very similar to the MP2 results. However, NbC<sub>3</sub> differs from LaC<sub>3</sub> in that another structure called the fan structure is lower in energy compared to the kite structure. The linear structure was assumed to be the ground state for LaC<sub>3</sub> in thermodynamic experiments.<sup>3–5</sup> The kite isomer comes out to be the ground state of YC<sub>3</sub>. Consequently, NbC<sub>3</sub> differs significantly from other early transition metal carbides such as LaC<sub>3</sub> and YC<sub>3</sub>.

**NbC<sub>4</sub>.** Tables 3 and 4 consist of our computed results on NbC<sub>4</sub> at different levels of theory. As seen from Table 3, the ground state for the NbC<sub>4</sub> cluster is a <sup>2</sup>B<sub>1</sub> (C<sub>2v</sub>) electronic state with a ring structure shown in Figure 1. However, the <sup>2</sup>A<sub>1</sub> state with the same structure is only 0.07 eV above this state, suggesting near-degeneracy of the two states. Analogous to NbC<sub>3</sub>, the linear structure of NbC<sub>4</sub> with a quartet state is 1.07 eV higher than the ring structure. Other structures, such as the kite structure, the T-structure, and the A-structure in Figure 1, are considerably higher in energy for NbC<sub>4</sub>. Unlike NbC<sub>3</sub>, the kite and the T structures are considerably higher in energy for NbC<sub>4</sub>.

As seen from Table 4, the CASSCF and MRSDCI techniques also predict the <sup>4</sup>B<sub>1</sub> and <sup>2</sup>A<sub>1</sub> states to be nearly degenerate consistent with the DFT prediction. In fact, at the CASSCF level, the <sup>2</sup>A<sub>1</sub> electronic state is slightly lower in energy compared to the <sup>4</sup>B<sub>1</sub> state. The MRSDCI+Q result is

quite close to the MRSDCI result, thus providing confidence in the MRSDCI technique and the completeness of the reference space.

Hay and co-workers<sup>43</sup> have employed RHF and MP2 computations on Nb<sub>4</sub>C<sub>4</sub> and Nb<sub>4</sub>C<sub>4</sub><sup>+</sup> species with a *T<sub>d</sub>* symmetry. It is interesting to note that their computed Nb—C bond distance of 2.013 Å in their structure is quite close to our Nb—C distances in NbC<sub>4</sub> and other niobium carbide clusters that we report here.

**NbC<sub>5</sub>.** Our computed DFT results are shown in Table 5 for NbC<sub>5</sub>. Analogous to smaller carbide clusters, NbC<sub>5</sub> exhibits a ring structure as the ground state with a <sup>2</sup>A<sub>1</sub> state, but the linear structure becomes energetically closer to the ring structure, as seen from Table 5. The kite structure is also more stabilized relative to smaller clusters. The T-structure is particularly unfavorable. The competition of the linear structure with the ring structure is particularly interesting, as this becomes a viable candidate especially for larger clusters containing even number of carbon atoms.

The geometrical features exhibited by NbC<sub>n</sub> clusters differ from other smaller carbide clusters such as LaC<sub>n</sub><sup>23</sup> which exhibit a preference for linear geometries although the most stable complexes of LaC<sub>n</sub> have the fan structures.

An interesting feature that we note in Table 5 is that the Nb—C bond distances in the linear structures are usually shorter than the corresponding spin multiplets of the ring structures because Nb forms multiple bonds with carbon in the linear structure. The carbon—carbon bonds in the linear structures exhibit bond alternation analogous to the tail of the kite structures (see, Table 5).

Table 6 shows the CASSCF/MRSDCI energy separations for the ground and excited electronic states of the ring structure of NbC<sub>5</sub>. As seen from Table 6, although at the CASSCF level the <sup>4</sup>A<sub>1</sub>—<sup>2</sup>A<sub>1</sub> energy separation is only 0.51 eV at the MRSDCI level this energy separation becomes 0.92 eV very close to the DFT/B3LYP result of 0.84 eV. As seen from Table 6, for NbC<sub>5</sub> we also find other quartet and doublet electronic states, which are potential candidates for spectroscopic observations as optical transitions to some of these states are allowed.

**NbC<sub>6</sub>.** Table 7 shows the geometries and energy separations of the electronic states of NbC<sub>6</sub> with ring, linear, A, and the kite structures. A dramatic contrasting feature of NbC<sub>6</sub> is that

	<sup>4</sup> B <sub>2</sub>		3.47	

<sup>a</sup> Vertical at the equilibrium geometry of the <sup>2</sup>A<sub>1</sub> state of the ring structure.

it is the first Nb carbide cluster exhibiting a linear ground state, as seen from Table 7. The quartet state with a linear geometry prevails as the ground state of NbC<sub>6</sub> although the ring structure which is favored for the smaller niobium carbide clusters is only 0.13 eV above the linear quartet state. Note that for NbC<sub>5</sub> already the linear structure comes down in energy although it is still higher than the ring structure. The ring structure has two nearly-degenerate electronic states, namely, <sup>2</sup>B<sub>1</sub> and <sup>4</sup>B<sub>1</sub> states. Two electronic states with the A structure are also quite stabilized for NbC<sub>6</sub> although for smaller clusters, electronic states with this geometry are relatively higher in energy. On the basis of the agreement between the DFT/B3LYP technique and the CASSCF/MRSDCI techniques, all computations for larger clusters were carried out using the computationally less intensive DFT/B3LYP technique.

<sup>a</sup> For the R structure, a<sub>1</sub> represents the bond angle of C<sub>1</sub>–Nb–C<sub>2</sub>, a<sub>2</sub> represents the bond angle of Nb–C<sub>1</sub>–C<sub>3</sub> and Nb–C<sub>2</sub>–C<sub>4</sub>, a<sub>3</sub> represents the bond angle of C<sub>1</sub>–C<sub>3</sub>–C<sub>5</sub> and C<sub>2</sub>–C<sub>4</sub>–C<sub>6</sub>, a<sub>4</sub> represents the bond angle of C<sub>3</sub>–C<sub>5</sub>–C<sub>7</sub> and C<sub>4</sub>–C<sub>6</sub>–C<sub>8</sub>, a<sub>5</sub> represents the bond angle of C<sub>5</sub>–C<sub>7</sub>–C<sub>8</sub> and C<sub>6</sub>–C<sub>8</sub>–C<sub>7</sub>. For the K structure, a<sub>1</sub> represents the bond angle of C<sub>1</sub>–Nb–C<sub>2</sub>, a<sub>2</sub> represents the bond angle of Nb–C<sub>1</sub>–C<sub>3</sub> and Nb–C<sub>2</sub>–C<sub>4</sub>, a<sub>3</sub> represents the bond angle of C<sub>1</sub>–C<sub>3</sub>–C<sub>4</sub> and C<sub>2</sub>–C<sub>3</sub>–C<sub>4</sub>. For the A structure, a<sub>1</sub> represents the bond angle of C<sub>1</sub>–Nb–C<sub>2</sub>, a<sub>2</sub> represents the bond angle of Nb–C<sub>1</sub>–C<sub>3</sub> and Nb–C<sub>2</sub>–C<sub>4</sub>, a<sub>3</sub> represents the bond angle of C<sub>1</sub>–C<sub>3</sub>–C<sub>5</sub> and C<sub>2</sub>–C<sub>4</sub>–C<sub>6</sub>, a<sub>4</sub> represents the bond angle of C<sub>3</sub>–C<sub>5</sub>–C<sub>7</sub> and C<sub>4</sub>–C<sub>6</sub>–C<sub>8</sub>, a<sub>5</sub> represents the bond angle of C<sub>5</sub>–C<sub>7</sub>–C<sub>8</sub> and C<sub>6</sub>–C<sub>8</sub>–C<sub>7</sub>. For the T structure, a<sub>1</sub> represents the bond angle of C<sub>2</sub>–C<sub>1</sub>–C<sub>3</sub>, a<sub>2</sub> represents the bond angle of C<sub>1</sub>–C<sub>2</sub>–C<sub>4</sub> and C<sub>1</sub>–C<sub>3</sub>–C<sub>5</sub>, a<sub>3</sub> represents the bond angle of C<sub>2</sub>–C<sub>4</sub>–C<sub>6</sub> and C<sub>3</sub>–C<sub>5</sub>–C<sub>7</sub>, a<sub>4</sub> represents the bond angle of C<sub>4</sub>–C<sub>6</sub>–C<sub>8</sub> and C<sub>5</sub>–C<sub>7</sub>–C<sub>8</sub>.

The C–C bonds exhibit bond alternation for the linear and ring structures. This is consistent with the delocalization of the  $\pi$ -electrons in the C–C framework. The Nb–C distance is the shortest for the linear structure, as seen from Table 7.

**NbC<sub>7</sub>.** Table 8 shows the computed properties and energy separations of the electronic states of NbC<sub>7</sub>. It can be seen from Table 8 that, unlike NbC<sub>6</sub>, the NbC<sub>7</sub> cluster exhibits a ring structure with a <sup>2</sup>A<sub>1</sub> state as the ground state. The quartet state is only 0.34 eV higher than the doublet state for the NbC<sub>7</sub> cluster. The electronic states with the linear structure are

substantially higher in energy. In fact, the lowest electronic state with the linear geometry is even higher than the lowest state with the A-structure for NbC<sub>7</sub>. This suggests a trend of odd–even alternation in that only for even  $n$  the linear structure appears to be favored, whereas for odd values of  $n$ , the ring structures are decisively more stable than the linear structures.

It may be seen from Table 8 that for the ring structure the doublet–quartet energy separation is 0.34 eV for NbC<sub>7</sub>, whereas the two electronic states are nearly degenerate for NbC<sub>6</sub>. The near-degeneracy of the quartet and doublet electronic states may

**Figure 2.** Plot of quartet-doublet energy separations for the ring structures of  $\text{NbC}_n$  for  $n = 3-8$ .

also be seen for other smaller even-numbered carbide clusters, whereas odd numbered carbide clusters exhibit a considerably larger energy splitting.

**$\text{NbC}_8$ .** Table 9 consists of the properties and energy separations of the electronic states of  $\text{NbC}_8$ . The  $\text{NbC}_8$  cluster exhibits a ring structure with a  $^4\text{B}_1$  state as the ground state, whereas the linear states are not too far from the ring structures. The doublet state is only 0.11 eV higher than the quartet state for the  $\text{NbC}_8$  cluster. The doublet and quartet states of the ring structure are very close in energy for the ring structure. The A-structure is also more stabilized relative to smaller clusters.

The analysis of the geometrical and electronic trends for the niobium carbide clusters clearly suggests a general trend of odd-even alternation that we briefly discussed above. That is, for even numbered clusters the energy separations between the ring and linear structures are rather small; in contrast, the odd clusters exhibit considerably larger energy separations for the linear structures. In fact,  $\text{NbC}_6$  is very special in having a linear ground-state structure in contrast to the other carbides, which exhibit ring structures as the ground states.

We have plotted the quartet-doublet energy separations for the  $\text{NbC}_n$  clusters as a function of  $n$  for the ring structure in Figure 2. A striking feature seen from Figure 2 is odd-even alternation in that for even  $n$  clusters the quartet electronic state is close to the double state, whereas for the odd clusters the doublet electronic states are significantly lower in energy. It may be seen from Table 8 that for the ring structure the doublet-

quartet energy separation is 0.34 eV for  $\text{NbC}_7$ , whereas the two electronic states are nearly degenerate for  $\text{NbC}_6$ . The closer energy of the quartet and doublet electronic states may also be seen for other smaller even-numbered carbide clusters, whereas odd numbered carbide clusters exhibit a considerably larger energy splitting, as seen from Figure 2.

**Computed Thermodynamic Properties and Vibrational Frequencies.** Experimental calculation of thermodynamic functions proceeds through the second or third law methods. These techniques require some knowledge of the structure of the molecule under consideration. Our computed geometries would be quite useful in calculating these properties from experimentally derived data.

The third-law enthalpies for the reaction  $\text{Nb(g)} + n\text{C(graphite)} = \text{NbC}_n(\text{g})$  as a function of temperature are given by

$$\Delta H_0^0 = -RT \ln K_p(T) - T\Delta[(G_T^0 - H_0^0)/T]$$

where  $K_p(T)$  is the equilibrium constant,  $\Delta[(G_T^0 - H_0^0)/T]$  is the Gibbs energy function (GEF) change for the reaction. The heat content function as a function of temperature is defined as  $[(H_T^0 - H_0^0)]$ . Consequently, it would be useful to compute the Gibbs free energy functions and enthalpies as a function of temperature so that these results could be used in any potential experimental thermodynamic measurements. Theoretically computed Gibbs free energy functions and heat capacity functions are shown in Table 10.

The theoretically determined heat content functions depend mainly on the quality of the electronic energy calculations. On the basis of our past computations on other transition metal carbides, we believe that both MRSDCI and DFT/B3LYP techniques yield good thermodynamic data. The computed results in Table 10 were derived from the MRSDCI results for the ground and excited states for  $\text{NbC}_n$  up to  $n = 5$  and for larger clusters the DFT data on the ground and excited states were utilized.

As seen from Table 10, an interesting feature is that the GEF and heat capacity functions for  $\text{NbC}_6$  at 298 K is unusually larger in magnitude. This is also consistent with its linear ground-state geometry compared to other clusters, which exhibit ring ground-state geometries.

Table 11 reports the computed vibrational frequencies of the normal modes of the smaller clusters and the corresponding infrared intensities. As seen from Table 11, of the six normal modes for  $\text{NbC}_3$ , three modes are very intense, two modes are

moderately intense, and one mode is weak. The three prominent features of NbC<sub>3</sub> occur at 470, 634, and 1523 cm<sup>-1</sup>, respectively. There are very intense vibrational modes for other larger clusters, which are potentially observable in the IR spectra.

**The Nature of Bonding in NbC<sub>n</sub>.** The bonding in NbC<sub>n</sub>, especially in the region where Nb–C bonds are formed is primarily determined by charge transfer from Nb to C and back transfer from C to Nb. The Nb–C bonds thus exhibit ionic character, as a consequence of electronic charge transfer from Nb to the carbons. Most of the charge transfer goes to the immediate neighbors of Nb. The general trend is that the electron transfer from Nb is larger when it is bound to two or more carbon atoms in contrast to a terminally bound Nb. The ionicity of the Nb–C bonds is directly proportional to the extent of charge transfer. This results in large dipole moments for the electronic states of NbC<sub>n</sub>. For example, the ground-state dipole moments of NbC<sub>4</sub> and NbC<sub>5</sub> clusters are 6.3 and 7.7 D, respectively with the dipole vector in the Z direction with Nb<sup>+</sup>C<sup>-</sup> polarity.

The Mulliken populations of the clusters are consistent with the charge transfer from Nb to C. For example, the gross Mulliken populations of Nb in NbC<sub>4</sub> and NbC<sub>5</sub> are 4.11 and 3.92, respectively. These values deviate from the natural Nb population of 5.0 suggesting strong electron transfer from Nb to C. It can be seen that the charge transfer from Nb is mainly from its 5s orbital to the C(2p) orbital. It is quite interesting that the 4d orbital of Nb does not participate in the charge-transfer process. The electron densities of the 4d and 5p orbitals of Nb are enhanced due to rearrangement of orbitals upon bond formation and back transfer of electronic charge from C to Nb(4d) and Nb(5p) due to pπ–pπ and dπ–pπ back-bonding. For example, the carbon atoms in NbC<sub>4</sub> exhibit gross populations of 4.23 and 4.21. Likewise, the carbon atoms in NbC<sub>5</sub> exhibit gross populations of 4.3, 4.28, and 3.93. The single carbon atom farthest away from Nb in the NbC<sub>5</sub> ring structure has the smallest population. It is interesting that charge transfer from Nb to the nearest carbons attached to it is delocalized at least to the second neighbors. It is also quite interesting that the Nb(5p) populations are between 0.14 and 0.3. For example, the Nb(5p) populations in NbC<sub>4</sub> and NbC<sub>5</sub> are 0.19 and 0.14, respectively in their ground states. Thus, the Nb atom deviates from its atomic population not only due to charge transfer from Nb to carbons but also due to rearrangement of the atomic populations among the 5s, 5p, and 4d orbitals due to back transfer from C to Nb and hybridization.

Table 12 shows the leading configurations of the electronic states of NbC<sub>n</sub>. As seen from Table 12, the <sup>2</sup>A<sub>1</sub> ground state of NbC<sub>3</sub> with the ring structure has a leading configuration with a single electron in the 6a<sub>1</sub> orbital, all other lower energy orbitals being doubly occupied. The <sup>4</sup>B<sub>2</sub> state arises from the promotion of an electron from the 1a<sub>2</sub> orbital to the 3b<sub>1</sub> orbital relative to the ground state. On the other hand, <sup>6</sup>A<sub>1</sub> state arises from another excitation of 4b<sub>2</sub> into 7a<sub>1</sub> in addition to the 1a<sub>2</sub> to 3b<sub>1</sub> excitation.

The highest occupied and lowest unoccupied MOs of NbC<sub>3</sub> can be described as follows. The 1a<sub>2</sub> orbital can be described as

$$1a_2 = \text{Nb}(4d_{xy}) + C_2(2p_x) - C_3(2p_x)$$

where C<sub>2</sub> and C<sub>3</sub> atoms are equivalent. The 4b<sub>2</sub> orbital can be expressed as

$$4b_2 = \text{Nb}(4d_{yz}) + C_2(2s) - C_3(2s) + C_2(2p_y) + C_3(2p_y)$$

whereas the 6a<sub>1</sub> orbital is composed of

$$6a_1 = \text{Nb}(4d_{z^2-(x^2+y^2)}) + \text{Nb}(5s)$$

The lowest unoccupied 3b<sub>1</sub> molecular orbital (LUMO) is composed of

$$3b_1 = \text{Nb}(4d_{xz}) + C_1(2p_x)$$

The singly occupied 6a<sub>1</sub> orbital is thus predominantly on Nb. The above compositions of the occupied orbitals are consistent with the description of bonding and Mulliken populations.

We expect the spin-orbit splittings of NbC<sub>n</sub> to be rather small on the basis of our previous estimate for NbC<sub>2</sub> from the atomic Nb splitting. The Nb <sup>6</sup>D(4d<sup>4</sup>5s<sup>1</sup>) ground-state splits into *J* = 1/2, 3/2, 5/2, 7/2, and 9/2 atomic states by 1050 cm<sup>-1</sup> between the highest and lowest *J* states. On the other hand, the <sup>4</sup>F(4d<sup>3</sup>5s<sup>2</sup>) spin-orbit splitting is 1663 cm<sup>-1</sup>. Because the Nb Mulliken populations of the ground state of NbC<sub>2</sub> are closer to the 4d<sup>4</sup>5s<sup>1</sup> configuration rather than 4d<sup>3</sup>5s<sup>2</sup> due to the charge transfer from Nb to C, the ground-state spin-orbit splitting between the two E<sub>1/2</sub> states of NbC<sub>2</sub> was estimated to be about 400 cm<sup>-1</sup>. Therefore, we do not expect the spin-orbit splitting to be large for NbC<sub>n</sub> clusters.

## V. Conclusion

We have reported the results of the CASMCSCF/MRSDCI computations of NbC<sub>n</sub> for *n* = 3–5 and DFT/B3LYP computations for the doublet, quartet, and sextet electronic states of NbC<sub>n</sub> for *n* = 3–8. We have considered five different geometries, viz., ring (R), linear (L), kite (K), Nb-terminally bound to a C<sub>n</sub> ring (T), and a structure with C–Nb–C bridge fused with a C<sub>n</sub> ring (A). We find that the NbC<sub>n</sub> clusters exhibit an odd–even alternation pattern in that for even *n*, the linear and ring structures are close in energy, while the odd-*n* clusters exhibit substantially lower ring structures. Among the clusters considered here, NbC<sub>6</sub> was found to be very special in having a linear geometry as the ground state. We have computed the equilibrium geometries, energy separations of the low-lying electronic states, Gibbs free energies, and the heat capacity functions as a function of temperature. The DFT/B3LYP technique was found to yield geometries and energy separations in overall agreement with the CASMCSCF/MRSDCI techniques. The nature of bonding in these carbide clusters was found to be very ionic with Nb<sup>+</sup>C<sup>-</sup> bonding facilitated by charge transfer from Nb(5s) to C(2p). This was accompanied by back transfer from C(2p) to Nb(4d) and Nb(5p) through ππ–ππ and ππ–δπ bonding.
