Versatile nanostructures, including metal–organic frameworks and carbon-based materials, have been designed and synthesized for specific targets of material science and engineering. More significantly, several recent studies have reported the adsorption of magnetic molecules on a nanostructured surface and highlighted the unusual magnetic properties of these arrangements. The unique inclusion and coupling phenomena of gaseous magnetic guest molecules into low-dimensional microphases of nanostructured surfaces have been detected in the configurations of cages, tubes, and wires with the aim of controlling the properties of the material, including its magnetism or reactivity, thereby creating unusual and discrete magnetic patterns. In addition, magnetic O₂ molecules reveal distinctive magnetic behavior when they undergo 3D solidification of the α , β , and γ phases or when they occupy the empty enclosing spaces of clathrate crystals such as a β -quinol compound.^{1–5} In the past few years, multiple studies of O₂ magnetism have confirmed that low-dimensional O₂ confinement in nanostructures such as the 2D O₂-filled nanostructure in graphite and 1D O₂ dimers adsorbed in metal–organic frameworks substantially but not completely destroy the inherent antiferromagnetism of pure solid O₂.^{6–10}

Here we demonstrate that the selective injection of magnetic O₂ and nonmagnetic tetrahydrofuran (THF) molecules into the water-ice cages of clathrate hydrates can modify the inherent magnetism. Ripmeester et al.¹¹ examined the spin–lattice relaxation of THF clathrate hydrate in the presence of O₂, analyzing its NMR behavior. However, the present study is focused on revealing two unique phenomena of the magnetic transition (antiferromagnetic to ferromagnetic) and long-time relaxation occurring in these clathrate hydrates. First, the binary THF and O₂ clathrate hydrate [(THF + O₂)*] was synthesized by exposing O₂ molecules to pure THF clathrate hydrate [(THF)*], with the occupation of magnetic O₂ in sII-S (5¹², cage occupancy $\theta_{\text{sO}_2} \approx 0.4$) and nonmagnetic THF in sII-L (5¹⁶, $\theta_{\text{L,THF}} \approx 1.0$). On the other hand, the pure O₂ clathrate hydrate [(O₂)*] forms stably by enclosing magnetic O₂ in both sII-S ($\theta_{\text{sO}_2} \approx 0.8$) and sII-L ($\theta_{\text{LO}_2} \approx 1$). The crystalline structure and guest occupancy of these clathrate hydrates were analyzed using neutron powder diffraction [Figure S1 in the Supporting Information (SI)]. The icy magnetic 3D superstructure is composed of two magnetic sublattices, namely, a tetrahedral sublattice formed by the sII-S cages and a diamond-like sublattice formed by the sII-L

Figure 1. (a) Superstructure composed of guest molecules in both sII-S (orange balls) and sII-L cages (blue balls). (b) Tetrahedral sublattice composed of O₂ molecules in sII-S cages. Remarkably, the O₂ molecules filled in the sII-S cages form a network of 1D molecular oxygen chains along the centers of the sII-S cages, thus creating a pyrochlore superstructure of corner-sharing tetrahedral elements that closely follows the spin-ice materials of Ho₂Ti₂O₇ and Dy₂Ti₂O₇. (c) Diamond-like sublattice composed of THF or O₂ molecules in sII-L cages. In (a)–(c), the line connections between two molecules do not represent chemical bonds but instead are eye-guides to show the 3D superstructure clearly.

cages (Figure 1), as clearly observed in antiferromagnetic materials and the pyrochlore lattices of spin-ice materials.¹² More specifically, the confined magnetic O₂ molecules that constitute a 3D channel induce two different clathrate hydrates to create a tetrahedral sublattice [(THF + O₂)*] and both tetrahedral and diamond-like sublattices [(O₂)*]. Here, (THF + O₂)* reveals a relatively low O₂ population in an icy crystalline matrix, resulting in the creation of a substantial number of empty cage sites neighboring the confined O₂ molecules with imperfect 3D channels.

In order to explore the magnetic properties of O₂ in clathrate hydrates, magnetic susceptibility [$\chi(T)$] was measured. Powder samples were packed into a quartz tube and then mounted on a Quantum Design Magnetic Property Measurement System (MPMS) or Physical Property Measurement System (PPMS) at 150 K. The measured ac/dc magnetic properties of O₂ molecules forming the sII 3D superstructures of (THF + O₂)* and (O₂)* are identified as completely different from the antiferromagnetism of solid or confined 1D or 2D O₂ reported previously (Figure S2 in the SI). For (THF + O₂)* and (O₂)*, the dc magnetic susceptibility [$\chi_{\text{dc}}(T)$]

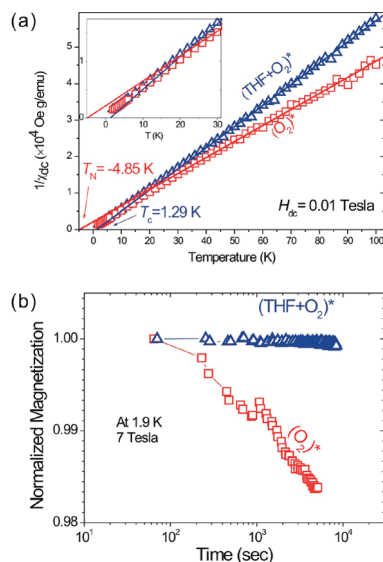

Figure 2. (a) Plots of $1/\chi_{dc}(T)$ vs T for $(\text{THF} + \text{O}_2)^*$ and $(\text{O}_2)^*$ measured at $H_{dc} = 0.01$ T; the inset shows a magnified view of low-temperature region. The solid lines are the Curie–Weiss fits to the measured data over the temperature range 20–100 K. (b) Long-time relaxation behavior of the magnetization $M(t)$ for $(\text{THF} + \text{O}_2)^*$ and $(\text{O}_2)^*$. The sample was initially cooled to 1.9 K under 0 T, and then the magnetization was measured as a function of time after setting the field to 7 T.

curves appear to be nearly paramagnetic, but they display a slightly different feature compared with typical paramagnets in the low-temperature region. The zero-field O_2 magnetic moments tend to be aligned randomly as a result of thermal fluctuations, while the high-field (7 T) ones imply field-induced alignment. A clear dissimilarity might be extracted by considering the simple Curie–Weiss law.

The $1/\chi(T)$ curve for $(\text{THF} + \text{O}_2)^*$ shows an upward deviation from linearity in the low-temperature region, while a slight downward tendency is observed for $(\text{O}_2)^*$ (Figure 2a and Figure S3 in the SI). From the fits to the Curie–Weiss law [$1/\chi \propto (T - T_{C,N})$], where $T_{C,N}$ represents either the Curie temperature T_C or the Néel temperature T_N], the $1/\chi(T)$ for $(\text{THF} + \text{O}_2)^*$ was observed to exhibit ferromagnetic-like behavior with $T_C = +3.25$ K (ac) and $+1.29$ K (dc). In contrast, the antiferromagnetic-like feature appears for $(\text{O}_2)^*$, with $T_N = -4.45$ K (ac) and -4.85 K (dc). For a clearer understanding of the contradictory magnetic patterns of $(\text{THF} + \text{O}_2)^*$ and $(\text{O}_2)^*$, which have identical structures (cubic, $Fd\bar{3}m$) but exhibit dissimilar O_2 populations, the magnetic interactions in each clathrate hydrate must be taken into account. The O_2 molecules in $(\text{THF} + \text{O}_2)^*$ are characterized by negligible magnetic coupling between neighboring molecules, as in a typical paramagnet, leading to field-induced saturation behavior as in typical ferromagnets. In contrast, a weak antiferromagnetic interaction between O_2 molecules prevails in $(\text{O}_2)^*$. This unique magnetic pattern comes from either direct coupling between guest O_2 molecules behaving dynamically in linear nanochannels consisting of consecutively stacked cages, indirect coupling between host and guest oxygens, or both.

Furthermore, a distinctive magnetic property difference between $(\text{THF} + \text{O}_2)^*$ and $(\text{O}_2)^*$ can be seen directly from the field-dependent magnetization [$M(H)$] patterns. $(\text{THF} + \text{O}_2)^*$ possesses 6.4 O_2 molecules/unit cell on average ($6.4\text{O}_2 \cdot 8\text{THF} \cdot 136\text{H}_2\text{O}$), whereas $(\text{O}_2)^*$ has 20.8 O_2 molecules/unit cell ($20.8\text{O}_2 \cdot 136\text{H}_2\text{O}$ with a 15 wt % hexagonal ice phase: 12.8 O_2 in sII-S and 8 O_2 in

sII-L). At this stage, a key question arises, namely, how the magnetization values [$1.95 \mu_B/\text{O}_2$ for $(\text{THF} + \text{O}_2)^*$ and $0.81 \mu_B/\text{O}_2$ for $(\text{O}_2)^*$] significantly differ at 1.9 K and 7 T, where saturated magnetization is observed (Figure S4 in the SI). Surprisingly, it was found that the occupancy number of O_2 in $(\text{O}_2)^*$ is much higher than that in $(\text{THF} + \text{O}_2)^*$, despite the fact that their magnetization values are reversed. These magnetic data indicate that the O_2 populations in the small and large cages greatly affect the magnetic coupling of $(\text{THF} + \text{O}_2)^*$ and $(\text{O}_2)^*$, and thus, their distinct magnetic patterns were observed. In particular, the magnetization was measured as a function of time at 7 T and 1.9 K (Figure 2b). This long-time relaxation of magnetization [$M(t)$] also supports the dissimilarity between the magnetic property patterns of $(\text{THF} + \text{O}_2)^*$ and $(\text{O}_2)^*$. A significant feature is that the $(\text{O}_2)^*$ magnetization decreases as time elapses, whereas the $(\text{THF} + \text{O}_2)^*$ value remains constant. In contrast to the zero- or positive-slope $M(t)$ of typical ferromagnets or spin-glasses, such a negative time dependence of the $(\text{O}_2)^*$ magnetization strongly suggests a rearrangement of oxygen magnetic moments to minimize the total magnetic energy in an antiferromagnetic-like system.^{13,14} Interestingly, this molecular inclusion phenomenon may be exploited via the lattice or in molecular engineering to tune the host–guest interaction pattern of a clathrate hydrate matrix to synthesize ice-based magnetic materials. In terms of both science and engineering, water-ice-based clathrate hydrate structures are expected to open up new opportunities to develop functionalized icy materials with specific targets, as demonstrated here for the confined O_2 molecules forming the 3D superstructures of crossed X-channels.
